Abstract: In our image processing applications, we use a simulated annealing procedure to find configurations of geometric shapes that fit the best an image. This type of algorithm allows finding one of the global minima of an arbitrary function provided that the cooling schedule is logarithmic with the time. Since this type of cooling schedules is very slow, geometrical cooling schemes are used in practice. Geometrical schemes are however subject to some disadvantages that we discuss in this report. To overcome these disadvantages, we propose an adaptive cooling scheme. This heuristic is based on the analysis of the cooling scheme behavior in practice. In particular, we observe the presence of critical temperatures. To deal with these critical temperatures, we propose a cooling scheme that decelerates when such a temperature is detected, and accelerates otherwise. We present results on a real problem taken from our image processing applications.

Key-words: Image processing, shape extraction, spatial point process, simulated annealing, adaptive cooling schedule.

Recuit simulé adaptatif pour la détection d'objets dans les images

Résumé : Dans nos applications, nous utilisons des techniques de recuit-simulé pour trouver la configuration de formes géométriques qui décrit le mieux une image. Ce type d'algorithme permet de trouver l'un des minimum globaux d'une fonction, dès lors que le schéma de décroissance de la température est logarithmique. La lenteur rédhibitoire de ce type de schéma impose en pratique l'utilisation d'une décroissance géométrique. Le schéma de décroissance géométrique présente toutefois des défauts que nous décrivons dans ce rapport. Pour pallier ces inconvénients, nous proposons un schéma de décroissance adaptatif. Ce schéma est construit à partir d'observations expérimentales. En particulier, nous observons la présence de températures critiques correspondant à des moments cruciaux du processus d'optimisation. Le schéma que nous proposons repose sur la détection de telles températures. Le schéma de refroidissement proposé ralentit lorsqu'une température critique est détectée, et accélère autrement. Nous présentons des résultats sur des problèmes réels tirés de nos applications en traitement d'images.

Mots-clés : Traitement d'images, extraction de formes, processus ponctuels spatiaux, recuit-simulé, schéma de décroissance adaptatif.

1 Introduction

In our image processing applications, we focus on the task of automatically detecting objects in real images. In [17, 16] we propose different models for detecting buildings from Digital Elevation Models (DEMs). We consider configurations of random geometric shapes (e.g. of rectangles, segments or both.) We use a spatial point process framework which has the following advantages. First it allows considering an unknown number of objects, and therefore does not require a precise knowledge on the number of objects to be detected. Moreover, spatial point processes can be specified through a density. The notion of a *probability density function* is essential for modeling tasks. The nice thing about spatial point process models is that the distribution of a Poisson point process can play the analog role to Lebesgue measure for real random variables. This notion of spatial point process density for instance enables the inclusion of a *prior knowledge* within the extraction procedure through a Bayesian model. Considering exponential families, we focus on sufficient statistics that account for the spatial repartition of objects in the scene. Examples of such statistics are the number of aligned rectangles and the number of connected segments.

Alternatively, these models can be written under a Gibbs form, consisting in the *partition function* (normalizing constant) along with the system's energy function. This energy is actually divided into two terms. First, *the data term* quantifies the quality of a configuration of objects with respect to the data. Second, *the internal field* acts on the repartition of objects and allows introducing a basic knowledge on patterns of interest through the definition of interactions. These two parts play the role of a Likelihood and a prior model in a Bayesian framework.

As a result of this modeling step, the energy is usually highly complex and exhibits numerous local minima. We consequently use a *simulated annealing* procedure based on a Hastings Metropolis scheme. The first advantage of this algorithm is that it can be applied to cases where the normalizing constant is not known. The second advantage is that the procedure provides a global minimum of the energy. However, the latter result only holds for specific cases that are not met in practice.

The simulated annealing procedure has been extensively used over the years. Originally proposed by S. Kirkpatrick and al in [11], the method quickly found a great audience outside the optimization community and is one of the few optimization methods widely known in very different fields. General overviews and discussion can be found in [24, 5, 9, 2, 7]. Originally proposed through an analogy with thermodynamics, the method has been subject to deep analysis of its convergence properties (see [1, 12, 13, 27, 14]). In image processing, the method has been recurrently associated with Markov Random Fields (see [28] and references herein). The basic idea is to drive an exploring process towards one of the points of global minima. The process is usually compared (see [11]) with the simulation of a system of particles that goes from high temperatures to a null temperature. Cooling the system slowly enough result in freezing the particles in the state achieving the global minimum of energy. However, the cooling schedule needs to be logarithmic, meaning that any arbitrary temperature is reached in an exponential time, making the procedure tremendously slow. In practice, geometric cooling schedules are therefore employed. The issue of an optimal cooling scheme has been the subject of many works. In [21] toy examples are used to derive analytical results that are compared to the usual assertions. Other works on cooling schedules include [4, 10, 22].

In our case, these geometrical cooling schemes face some disadvantages that we describe in this report. In particular the presence of critical temperatures considerably degrades the result quality. We present an adaptive cooling scheme based on experimental observations that allows slowing down the cooling scheme around such critical temperatures.

In Section 2 we describe briefly our image processing framework. In Section 3 we present the simulated annealing procedure, and different usual cooling schedules. In Section 4 we expose experimental observations that lead us to propose a new adaptive scheme in Section 5. We present results on a real problem taken from [16] in Section 6 and detail the possible future work in Section 7.

2 Image, shapes, point processes and energy

We model a 2D image as a *continuous* bounded set $K = [0, X_{1_{max}}] \times [0, X_{2_{max}}]$, and note $x = (c_1, c_2)$ a point of K .

2.1 Random configuration of points

A *configuration of points* \mathbf{x} (noted in bold) is a unordered set of points in K

$$\mathbf{x} = \{x_1, \dots, x_{n(\mathbf{x})}\}, \quad x_i \in K, \quad (1)$$

where $n(\mathbf{x}) = \text{card}(\mathbf{x})$ denotes the number of points in the configuration. We note \mathcal{C} the set of all possible finite configurations. Let consider a mapping from an abstract probability space $(\Omega, \mathcal{A}, \mathbf{P})$ to the set of configurations \mathcal{C} . Due to the finiteness of the considered configurations along with the boundedness of K , the σ -algebra associated with \mathcal{C} is well defined (see [26] for details.)

A *point process* \mathbf{X} of points in K is such a measurable mapping

$$\forall \omega \in \Omega, \quad \mathbf{X}(\omega) = \{x_1, \dots, x_n, \dots\} \quad x_i \in K. \quad (2)$$

Accordingly, a point process is a random variable whose realizations are random configurations of points.

2.2 Poisson point process

The most random point process (in the entropy sense) is the *Poisson point process*. Let $\nu(\cdot)$ be a positive measure on K . A Poisson point process \mathbf{X} with intensity $\nu(\cdot)$ verifies the following properties

- for every Borel set $A \subset K$, the random variable $N_{\mathbf{X}}(A)$, giving for the number of points of \mathbf{X} falling in the set A , follows a discrete Poisson distribution with mean $\nu(A)$

$$\mathbf{P}(N_{\mathbf{X}}(A) = n) = e^{-\nu(A)} \frac{\nu(A)^n}{n!}, \quad (3)$$

- and for every finite sequence of non intersecting Borelian sets B_1, \dots, B_p the corresponding random variables $N_{\mathbf{X}}(B_1), \dots, N_{\mathbf{X}}(B_p)$ are independent.

Poisson point processes are useful in our setup due to their analog role to Lebesgue measures on \mathbb{R}^d . As we detail it later, it is indeed possible to define point processes by specifying their density with respect to the distribution of a reference Poisson point process.

2.3 Marked point process

The configurations of points described so far only include simple points of \mathbb{R}^2 . To describe random configurations of geometrical objects, random marks are added to each point.

For instance, let consider the following mark set

$$M^r = \left[-\frac{\pi}{2}, \frac{\pi}{2}\right] \times [L_{\min}^r, L_{\max}^r] \times [l_{\min}^r, l_{\max}^r]. \quad (4)$$

Noting by x elements of $S_r = K \times M_r$, we consider the following parameterization describing rectangles

$$x \in S_r, \quad x = (c_1(x), c_2(x), \theta(x), L(x), l(x)), \quad (5)$$

where $(c_1(x), c_2(x))$, $\theta(x)$, $L(x)$ and $l(x)$ correspond respectively to the center position, the orientation, the length and the width of the rectangle x . A marked point process \mathbb{X} of rectangles is a point process on $S_r = K \times M_r$.¹ Note that in [16] we also consider a process of segments.

2.4 Density of a spatial point process

An attractive feature of spatial point processes is the possibility of defining a point process distribution by its *probability density function* (pdf). A Poisson point process can indeed play the analog role to Lebesgue measure on \mathbb{R}^d .

¹There is actually a further requirement that the restriction of \mathbb{X} to K , noted $\mathbb{X}|_K$, should also be a point process on K . In our case, this technical condition on the measurability of the mapping \mathbb{X} is satisfied since the sets K and S_r are bounded, see [26] for details.

Consider the distribution $\mu(\cdot)$ of a Poisson point process defined by its non atomic intensity measure $\nu(\cdot)$ and a mapping $h(\cdot)$ from the space of configurations of points \mathcal{C} to $[0, \infty[$. We consider the function $Z(\mu, h)$ defined as

$$Z = \int_{\mathcal{C}} h(\mathbf{x}) d\mu(\mathbf{x}). \quad (6)$$

If $Z < \infty$, the function $Z^{-1}h(\mathbf{x})$ can be seen as the density of a point process \mathbb{X} with respect to the reference Poisson process (see [26]).

For instance, assume that

$$h(\mathbf{x}) = \prod_{i=1}^{n(\mathbf{x})} \beta(x_i) \quad (7)$$

where $\beta(\cdot)$ is an *intensity* function from S to $]0, \infty[$. A point process \mathbb{X} defined by this density turns to be a Poisson point process with intensity

$$\nu'(A) = \int_A \beta(u) d\nu(u). \quad (8)$$

In this simple case, the probability density function $Z^{-1}h(\cdot)$ allows a change of intensity measure. This example actually belongs to the more general class of *exponential families*. Let $t(\cdot)$ be a mapping from \mathcal{C} to \mathbb{R}^k . It is possible to describe a class of point process densities by using a parameter $\theta \in \mathbb{R}^k$ together with the scalar product $\langle \cdot, \cdot \rangle$

$$h(\mathbf{x}) = e^{-\langle \theta, t(\mathbf{x}) \rangle} \quad (9)$$

Of course, the density is well defined if and only if $Z(\theta, \mu) < \infty$. In this work we introduce a density where points are not independent but are correlated by means of interaction energies. In our applications we usually consider the density from the energy point of view:

$$U(\mathbf{x}) = -\langle \theta, t(\mathbf{x}) \rangle. \quad (10)$$

2.5 Estimator and MCMC

In [15] we presented an MCMC algorithm generating samples of a point process \mathbf{X} defined by an unnormalized density $h(\cdot)$ along with a reference Poisson point process distribution. The obtained algorithm produces a Markov Chain $(X_t)_{t \geq 0}$ ergodically converging to the distribution of \mathbf{X} .

The procedure enables the computation of Monte Carlo values. Another possibility is to use the sampler within a *simulated annealing* framework providing a global maximum of the density $h(\cdot)$ as described in [25]. The estimator obtained is consequently the maximum density estimator

$$\hat{\mathbf{x}} = \text{Argmax } h(\cdot) \quad (11)$$

We detail these notions in Section 3.

2.6 Energy

In our applications [17, 16] we define models through the energy of a configuration of points. These models can be alternatively seen as exponential families, thereby allowing parameter estimation procedures (see [6]). The energy is defined over the set of configurations of objects

$$\begin{aligned} U : \mathcal{C} &\rightarrow \bar{\mathbb{R}} \\ \mathbf{x} &\rightarrow U(\mathbf{x}) \end{aligned} \quad (12)$$

Basically the energy models we consider are made of two parts

$$U(\mathbf{x}) = U_{data}(\mathbf{x}) + \rho U_{reg}(\mathbf{x}), \quad \rho > 0. \quad (13)$$

The data term $U_{data}(\mathbf{x})$ quantifies the relevance of the configuration \mathbf{x} with respect to the data, while $U_{reg}(\mathbf{x})$ acts on the geometric pattern of objects. For instance, in [17] we use a regularization term that favors alignments between rectangles.

2.7 Examples of result

We present here some results taken from [16]. We consider a process of rectangles and segments, and a prior model that favors a paving behavior of the rectangles as well as connection interactions between segments. Two samples of the prior model are presented in Figure 1. The data term is designed such that the segments are attracted by the discontinuities of the image while the rectangles by the homogenous areas. We also consider a term that favor interactions between both kind of geometric shapes, in order to make both informations (discontinuity and homogeneity) fit one each other. Figure 2 presents an extraction result on a Digital Elevation Model provided by the French National Geographic Institute (IGN).

Figure 1: Simulation result showing the influence of the internal field on the process of rectangles and segments.

Figure 2: From left to right. Digital Elevation Model of a part of Rennes, France (©IGN) that has been obtained by aerial stereovision, segment extraction result, and rectangle extraction result.

3 Simulated annealing

In this section, we describe the simulated annealing procedure. This type of algorithm has been widely used in image processing (see [28], for instance). We first present the greedy algorithm which is the simplest stochastic optimization algorithm, and expose the simulated annealing that can be intuitively seen as an extension of the former.

3.1 Greedy algorithm

The simplest way of minimizing $U(\cdot)$ is to use a greedy algorithm. This procedure starts from an arbitrary initial state X_0 . At each time step t , the current configuration $X_t = \mathbf{x}$ is randomly modified, resulting in a new configuration \mathbf{y} . The perturbation induces an energy variation

$$\Delta U = U(\mathbf{y}) - U(\mathbf{x}).$$

The greedy algorithm accepts to replace \mathbf{x} by \mathbf{y} only if $\Delta U \leq 0$, i.e. only if the perturbation has improved the current configuration. This rather simple procedure is then iterated. Addition, deletion, translation, rotation or modification of a randomly chosen object are examples of usual transformations. The major and obvious drawback of this algorithm is that it provides a local minimum that depends on the initial configuration as well as on the set of possible transformations.

3.2 Hastings Metropolis and simulated annealing

3.2.1 Generic Structure

Suppose we consider a point process \mathbf{X} defined by its energy $U(\cdot)$. Through the Gibbs relation, this energy leads to a density h known up to a normalizing constant. This density together with the distribution $\mu(\cdot)$ of the reference Poisson point process defines the distribution $\pi(\cdot)$ of \mathbf{X} .

The Markov chain $(X_t)_{t \geq 0}$ is defined by a starting point $X_0 = \{\emptyset\}$ and a Markovian transition kernel $P(F, \cdot)$ corresponding to the conditional distribution of $X_{t+1} | X_t = \mathbf{x}$. It results in a Markov chain $(X_t)_{t \geq 0}$ on the space of finite configurations of points \mathcal{C} .

Of course, $P(\cdot, \cdot)$ is designed in order to make the Markov Chain converge towards the desired distribution.

$$\|P^n(\{\emptyset\}, \cdot) - \pi(\cdot)\|_{TV} \rightarrow 0 \quad (14)$$

where $\|\cdot\|_{TV}$ notes the Total Variation norm (TV).

The Markov chain generated by the following algorithm satisfies this property. We actually have more accurate results, since we know that we can start from any configuration (Harris recurrence) and that the total variation tends to zero geometrically (geometric ergodicity), as detailed in [15].

3.2.2 Algorithm

The algorithm is based on a mixture of perturbation kernels $Q(\cdot, \cdot) = \sum_m p_m Q_m(\cdot, \cdot)$ where $\sum p_m = 1$ and $\int Q_m(\mathbf{x}, \mathbf{x}') \mu(d\mathbf{x}) = 1$. The algorithm iterates the following steps. We fix the current state X_t as $X_t = \mathbf{x} = \{z_1, \dots, z_n\}$.

- [1] Choose one of the proposition kernels $Q_m(\cdot, \cdot)$ with probability $p_m(\mathbf{x})$ and
- [2] sample \mathbf{x}' according to the chosen kernel $\mathbf{x}' \sim Q_m(\mathbf{x}, \cdot)$.
- [3] Compute the Green's ratio $R_m(\mathbf{x}, \mathbf{x}')$, function of the selected kernel Q_m , the original state \mathbf{x} and the proposed new state \mathbf{x}' . The ratio R_m is derived to make the Markov chain converge towards the desired distribution.
- [4] The proposition is accepted $X_{t+1} = \mathbf{x}'$ with a probability $\alpha_m(\mathbf{x}, \mathbf{x}') = \min(R_m(\mathbf{x}, \mathbf{x}'), 1)$ and rejected otherwise.

3.2.3 Perturbation kernels

The efficiency of the algorithm highly depends on the variety of possible transformations $Q_m(\mathbf{x}, \cdot)$.

Birth or death. This kind of perturbation first chooses with probability p_b and $p_d = 1 - p_b$ whether a point should be removed (death) or added (birth) to the configuration. If death is chosen, the kernel selects randomly one point u in \mathbf{x} and proposes $\mathbf{x}' = \mathbf{x} \setminus u$, while if birth is chosen, it generates a new point u according to the uniform measure $|\cdot|/|S|$ and proposes $\mathbf{x}' = \mathbf{x} \cup u$. The birth or death kernel is necessary and sufficient to insure the convergence of the Markov chain towards the target distribution.

Non jumping transformations. Non jumping transformations are transformations that first select randomly a point u in the current configuration and then propose replacing this point by a perturbed version v , $\mathbf{x}' = \mathbf{x} \setminus u \cup v$. Translation, rotation or dilation are examples of non jumping perturbations.

Birth or death in a neighborhood. We introduced this kind of transformation in [15]. The idea is to propose the removal or addition of interacting pairs of points with respect to one of the attractive relations such as the connection in the case of segments or alignment in the case of rectangles.

Green ratio. With each of these proposition kernels a mapping $R_m(.,.)$ from $\mathcal{C} \times \mathcal{C}$ to $(0, \infty)$ is associated. This value, named *Green ratio*, depends on the target distribution π . See [15, 16, 17] for derivations of Green ratios in specific cases.

3.2.4 Simulated annealing

To find a minimizer of the energy $U(.)$ we use a simulated annealing framework. Instead of generating samples of $h(.)$, we simulate $h^{\frac{1}{T_t}}(.)$. The temperature parameter T_t tends to zero as t tends to ∞ . Note that it is equivalent to the notation

$$f_t(\mathbf{x}) = Z_{T_t}^{-1} \exp\left(-\frac{U(\mathbf{x})}{T_t}\right). \quad (15)$$

If T_t decreases with a logarithmic rate, then X_t converges a.s. towards one of the global maximizers of $h(.)$. The temperature parameter constructs a sequence of probability measures that almost surely converges pointwise towards a set of Dirac measures putting with masses on the set of global minima. The logarithmic schedule gives Dobrushin conditions asserting the convergence of process towards this set of Dirac masses (see [25]).

3.3 Logarithmic cooling schedule

It is well known (see [8]) that if a logarithmic cooling schedule

$$T_t = \frac{C}{\log(1+t)}$$

is adopted, then the Chain converges towards a global minimum of the energy, provided that C is greater than the depth of the local minimum that is not a global minimum. It should be noted that in the case of simulated annealing applied to point process models a proof of convergence exists, based on a “birth or death” algorithm ([25]) but to our knowledge, such a proof does not exist in the case of a Metropolis-Hastings update type, although the extension should be straightforward.

3.4 Geometrical cooling schedule

The logarithmic schedule exhibits a major drawback: the time required to reach any temperature follows an exponential function. Since in practice we are limited by finite times, a common solution is to use a geometrical cooling schedule

$$T_t = T_0 A^t,$$

where $A < 1$ tunes the cooling speed.

Note that the quality of the proposition kernels is an important issue. As a consequence we design kernels such that the trajectory of the Markov chain is poorly correlated to insure a good exploration of the state space, see [16].

A very similar scheme is the piecewise constant geometrical scheme. The idea is to keep the temperature constant on steps and decrease it in precise instants. At first glance, this idea looks rather useless since it is equivalent to increase the constant A . However, this idea has a main advantage. The step on which the temperature is kept constant can be used to test whether the Markov Chain has converged or not, and thereby decrease the temperature accordingly. For instance, in [3], Brooks proposes decreasing the temperature only if the chain has converged. Of course, this idea requires the existence of a test on the chain convergence, which is not a simple problem (see [18]).

3.5 Adaptive schedules

In [4] the author presents a comparative study of different proposition kernels and cooling schedules that can be used for a set of academic simulated annealing problems (including the Ising model). An interesting formalism is proposed, representing the selection of an optimal cooling schedule as a control problem. In some simple cases it is possible to derive analytical solutions. Nevertheless, the complexity of our models make analytical results difficult to obtain. We therefore focus on more generic heuristics. We present here two interesting approaches that can be found in the litterature, although they failed in our case.

Reversibility. One of the ideas studied in [4], originally proposed in [23], is based on a slightly modified geometrical cooling scheme. Let consider some time intervals (steps) $t \in [n_i, n_{i+1}[$ indexed by i and the associated average energy

$$\langle U \rangle_i = \frac{1}{n_{i+1} - n_i + 1} \sum_{k=n_i}^{n_{i+1}} U(\mathbf{x}_k). \quad (16)$$

This average energy at step i can be seen as a statistic. A basic idea is to compare the measured average level to the previous one (namely $\langle U \rangle_{i-1}$) and decrease the temperature only if the new average energy is greater than previous one

$$T_{i+1} = \begin{cases} T_i & \text{if } \langle U \rangle_{i+1} \leq \langle U \rangle_i \\ AT_i & \text{if } \langle U \rangle_{i+1} > \langle U \rangle_i. \end{cases} \quad (17)$$

Basically, this scheme relies on the idea that the stability of the average energy is a good indicator of the chain convergence. This scheme is subject to two major problems. First the constant A needs to be adjusted properly, and second, the scheme is very slow in practice.

Constant thermodynamic speed. Another possibility is to design a scheme by extending the intuitive physical analogy of the simulated annealing procedure. One idea is to focus on the entropy of the system. We describe here a scheme detailed in [20, 19].

In addition to the average energy, let consider a second order statistic

$$\langle (\Delta U)^2 \rangle = \frac{1}{n_{i+1} - n_i + 1} \sum_{k=n_i}^{n_{i+1}} (U(\mathbf{x}_k) - \langle U \rangle_i)^2. \quad (18)$$

The variance can be linked to the thermic capacity

$$C(T) = \frac{\langle (\Delta U)^2 \rangle}{T^2}, \quad (19)$$

which turns to be the derivative of the system entropy

$$\frac{dS}{dT} = \frac{C}{T}.$$

As a consequence, the following scheme exhibits a constant entropy variation

$$T_{i+1} - T_i \propto \frac{T}{C} = \frac{T_i^3}{\langle U^2 \rangle_i - \langle U \rangle_i^2}.$$

The proportionality parameter needs to be carefully tuned. Loosely speaking, this scheme tends to limit the gap of temperature between two steps when the energy variation is important. In our case, this scheme did not work well: the choice of the constant appeared to be a major issue, especially in order to get finite computational times.

4 Experimental observations

We describe in this section some experimental observations. We use the model we presented in [16] and which we briefly described in Section 2.7.

4.1 Geometrical schedule

We show on Figure 3 different geometrical schemes with different parameters. Of course, the time needed to reach the threshold temperature ($T_{min} = 10^{-7}$) is a logarithmic function of the cooling parameter. Figure 4 presents the corresponding simulated annealing trajectories.

The trajectories are plotted in a specific way. We present the graph of the energy as a function of the temperature ($x(t) = -\log(T(t))$ and $y(t) = U(t)$). The main observation we can make is that for a specific temperature, the average energy is highly dependent on the cooling speed and that the faster the cooling speed, the higher the average energy.

Figure 3: Different piecewise constant geometrical cooling schedules (temperature as a function of time).

4.2 Convergence delay

Figure 4 exhibits an important phenomenon. For a given temperature, the current average energy is dependent on the preceding iterations. We call this phenomenon 'convergence delay'. This terminology underlines the fact that the process does not have enough time to reach the theoretical average energy level associated with a specific temperature

$$\langle U \rangle_{[t, t+\Delta t[} \geq \mathbb{E}_{T_t} [U(X_t)]. \quad (20)$$

4.3 Surfusion, critical temperature

We now describe a very interesting phenomenon. Suppose that the system is at a specific temperature T_t , with an average energy $\langle U \rangle_t$.

We tried an adaptive scheme based on propositions: a new temperature $T_{t+1} < T_t$ is first proposed, and then if some property is fulfilled (equilibrium test) the new temperature is accepted, and otherwise the temperature is set back to the previous temperature T_t for a set of iterations, before trying a new decrease.

Figure 4: Simulated annealing trajectories, corresponding to the cooling schedules presented in Figure 3. The faster the scheme, the higher the trajectory. We plotted $U(t)$ as a function of $-\log(T(t))$. Top: global view, bottom: close view.

Sometimes appears a phenomenon that we use to define of “critical temperature”. Although the temperature is set back to the previous one, the average energy does not come back to the previously observed value, even if until that point the simulation has been sufficiently slow to insure a good convergence.

We illustrate this instable behavior on Figure 5. An intuitive connection can be made with the physical phenomenon of surfusion, which is a delayed phase transition property: water can exists under temperature and pressure conditions where it should be ice, for instance, and a small perturbation can freeze it suddenly.

We present on Figure 6 a simulation using an adaptive scheme that does not account for critical temperatures. The system instability around the critical temperature leads to an abrupt energy decrease, although the temperature is kept constant.

From an experimental point of view, this behavior is very interesting. It seems that these critical temperatures concentrate huge gaps of average energy levels. The scheme we propose in this report tries to take advantage of this observation. We propose detecting such temperatures, and decrease brutally the cooling speed, in order to cross critical temperature as slowly as possible. On the other hand, we increase the speed of convergence between two critical temperatures.

Figure 5: Theoretical illustration of the critical temperature phenomenon. When the system stays, even very shortly, under a specific temperature, the average energy brutally decreases.

5 A new adaptive cooling scheme

5.1 Sub-periods

We consider steps of size Δ_t . Typically, we take in practice steps of length 10000, 20000 or 30000 iterations. A step is divided into L sub-steps of length δ_t . We usually take $L = 10$. The temperature can be decreased only at the beginning of a step.

We note $\langle U \rangle_i$ the average energy measure on the i th large step (length Δ_t) and $\langle U \rangle_{(i,k)}$ the average energy measured on the k th sub step of the i th step.

5.2 Balance test

In the scheme described by equation (17), the balance is tested using a large step. Balance is decided if the new average energy is larger than the previous one. In the case of complex systems, we consider this test to be to demanding. We rather propose to insure that it is possible to go back over the previous energy level during a short period of time. Figure 7 illustrates the test we use consequently. It can be decomposed as follows.

We consider that balance is lost between steps i and $i + 1$ if

$$N_{over} = \text{card}\{k \text{ s.t. } \langle U \rangle_{i+1,k} \geq U_{ref} - \epsilon\} < n_1 \quad \text{with} \quad U_{ref} = \langle U \rangle_i \quad (21)$$

where ϵ is a sensibility parameter. If there is at least n_1 sub-steps such that the corresponding average energy levels are greater than the average energy level of the previous step, we consider that balance is achieved. The ratio n_1/L therefore corresponds to the required ratio of excursion above the previous energy level. In practice, we took $n_1 = 1$ or $n_1 = 2$ with $L = 10$.

Figure 6: Simulation illustrating the critical temperature phenomenon. We used an adaptive scheme that makes the cooling speed decreases when needed. This deceleration is not large enough to account for the presence of a critical temperature ($T_{cr} \simeq 0.194$, $-\log(T_{cr}) \simeq 1.64$).

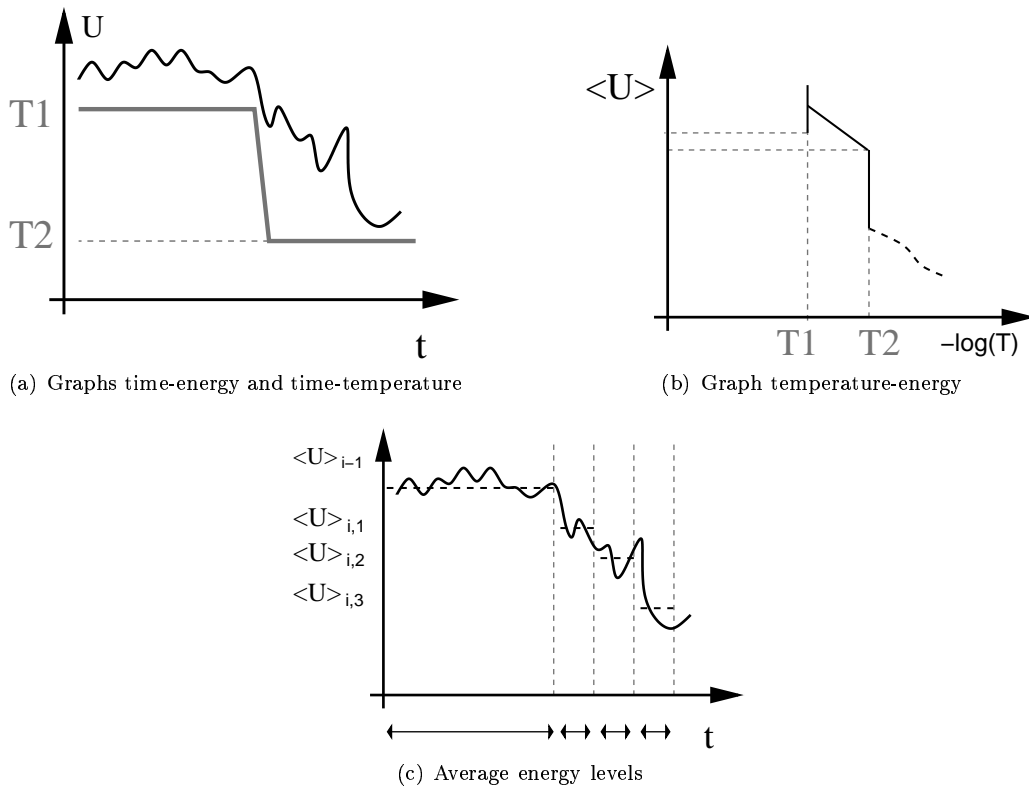

Figure 7: Example of a behavior we take into account. During the last step, a coming back over the previous average energy level is possible, although the new average energy is lower than the previous one.

5.3 Acceleration-deceleration

We propose slowing down the cooling scheme whenever balance is not achieved. For that purpose, we use the following iteration

$$A_{i+1} = A_i^r \quad \text{with } r < 1 \quad \text{if } N_{over} < n_1.$$

Note that when the constant A is increased, the cooling speed is decreased.

Similarly, when $N_{over} \geq n_2$, we consider that the temperature gap between i and $i+1$ is not large enough and we increase the cooling speed

$$A_{i+1} = A_i^{\frac{1}{r}} \quad \text{with } r < 1 \quad \text{if } N_{over} \geq n_2.$$

Of course the different parameters need to be tuned. In practice, we use $L = 10$, $n_1 = 1$, $n_2 = 5$ and $r = 0.85$. This values turned to be quite robust. Moreover, to avoid numerical problems resulting in $A_i = 1$, we impose an upper bound on A

$$\log(1 - A_i) \geq -16.$$

5.4 Critical temperature

The scheme presented so far works well in practice, but does not account for critical temperatures. The simulation presented in Figure 6 has been obtained with that particular scheme. As we mentioned earlier, the deceleration is not large enough around the critical temperature ($T_{cr} = 0.194$ on the example).

This behavior can be explained as follows. During the first attempts to decrease the temperature, the energy level brutally collapse. The balance test thereby detects that balance is not achieved, rejects any decrease of the temperature and increase the cooling parameter A . However, the new reference energy level U_{ref} is estimated while the system is still under the influence of its incursions at lower levels. The next cooling proposition can thus be wrongly accepted since the reference energy level estimation was biased.

As a consequence, when a cooling proposition is rejected, we propose stopping the cooling, in order to allow the system to come back to energy levels in accordance with the previous temperature. To that purpose, we propose testing the balance using the average energy level of the step before the first rejected cooling proposition.

Due to critical temperatures and the surfusion issue, it can happens that this test is never fulfilled. The energy level can indeed be stuck to a level way under the level that has been observed during the firsts staying at the previous temperature. We propose to reset the reference level energy if nb_{inhib} steps have finished without reaching the previous reference level U_{ref} .

5.5 Algorithm

We detail here the resulting algorithm.

```

 $T = T_{init}$  Initializations
 $T_{ref} = T_{init}$ 
 $r = 0.85$ 
 $tem_{ref} = 0$ 
 $U_{ref} = 0$ 

While  $T > T_{min}$  Beginning of a large step
   $nb_{dec} = 0$ 
   $U_{mes} = 0$ 
   $U_{average} = 0$ 
   $N_{over} = 0$ 

  If  $tem_{ref} = 1$  Temperature update
     $T_{ref} = T$ 
     $T = AT$ 

  For  $k = \{1, \dots, N\}$  Beginning of small step

    For  $l = \{1, \dots, \delta t\}$ 
      Simulate(system,  $T$ )
       $U_{mes} = U_{mes} + \text{Energy}$ 

     $U_{mes} = U_{mes} / \delta t$ 
     $U_{average} = U_{average} + U_{mes}$ 

    If  $U_{mes} > U_{ref} - \epsilon$ 
       $N_{over} = N_{over} + 1$ 

  If  $N_{over} \geq n_1$  then  $tem_{eq} = 1$  else  $tem_{eq} = 0$  balance is achieved

  If  $N_{over} \geq n_2$  then  $tem_{slow} = 1$  else  $tem_{slow} = 0$  going to slowly

  If  $tem_{ref} \leq 0$  then  $tem_{comingback} = 1$  else  $tem_{comingback} = 0$  inhibition

  If  $tem_{ref} < 1$ 
    If  $eq = 1$ 
       $tem_{ref} = 1$ 
    else
       $tem_{ref} = tem_{ref} + 1$ 

  If  $tem_{ref} = 1$  Update of  $U_{ref}$ 
    If  $tem_{eq} = 1$  or  $tem_{comingback} = 1$ 
       $U_{ref} = U_{average} / N$ 

  If  $tem_{eq} = 0$  decrease cooling speed
     $T = T_{ref}$ 
     $A = A^r$ 
     $tem_{ref} = -nb_{inhib} + 1$  the value of  $U_{ref}$  is blocked

  If  $tem_{slow} = 1$  and  $tem_{comingback} = 0$  the speed is increased
     $A = A^{1/r}$ 

```

Simulation	A	Δ_t	Needed T_{min}
a	0.9985	2000	20 millions iterations
b	0.9994	2000	35 millions
c	0.99994	2000	200 millions
d	adaptive	20000	250 millions

Table 1: Description of the different simulations.

5.6 Comments

We now detail some specific behaviors of the proposed scheme. Suppose first that the previous step $i-1$ resulted in a decrease of temperature. We therefore have a good estimate $U_{ref} = \langle U \rangle_{i-1}$ of the average energy over the preceeding period. At the beginning of the new period i , the cooling is tried using the current parameter A . As soon as the step i is finished, the behavior of the energy during the step is examined.

- If the balance test is positive, (i.e. $N_{plus} \geq n_1$), two possible cases can be distinguished:
 - either the energy has spent at least n_2 sub period over the reference energy U_{ref} ($N_{plus} \geq n_2$), resulting in a decrease of A (increase of the cooling speed),
 - or $n_1 \leq N_{plus} < n_2$, and A stays constant.

In both cases, the step i finishes with the update of the reference energy ($U_{ref} = \langle U \rangle_i$) and the reference temperature ($T_{ref} = T_i$). The temperature is then updated $T_{i+1} = AT_i$ and the step $i+1$ starts.

- If the balance test is negative, the temperature is set back to the reference ($T_{i+1} = T_{ref}$). The cooling parameter is increased ($A = A^r$) while the reference energy level U_{ref} is kept constant, i.e. $U_{ref} = \langle U \rangle_{i-1}$. Moreover, tem_{ref} is set to $tem_{ref} = -nb_{inhib} + 1$, meaning that the process will spend nb_{inhib} steps at the same temperature, except if the energy stays over U_{ref} during at least n_1 sub-steps,
 - in which case, the cooling goes on normally, using the new parameter A .
 - On the other hand, if nb_{inhib} steps have been spent at a temperature T_{ref} and without reaching the reference level U_{ref} long enough, the reference energy is updated ($U_{ref} = \langle U \rangle_{i+nb_{inhib}}$), the temperature kept constant ($T_{i+nb_{inhib}+1} = T_{ref} = T_{i-1}$), the cooling parameter A increased and a new inhibited cycle is started ($tem_{ref} = -nb_{inhib} + 1$).

6 Results and comments

We present in this section some results and compare the proposed cooling schedule to usual geometrical schemes. We optimize the model with two elements (rectangles and segments) that we proposed in [16]. The reference simulations were obtained using piecewise constant geometrical cooling schemes.

The problem considered here is really complex. The model is made of two types of objects, and several interactions. On this problem, the scheme 17 and the scheme with a constant thermodynamic speed are useless: they are so slow that after a week, the temperature was still stuck at an intermediary level, around the first critical temperature.

6.1 General behavior

The first result has been obtained with $nb_{inhib}=1$, $L = 20000$, $N = 10$, $n_1 = 1$, $n_2 = 5$.

We compare 4 simulations whose trajectories are presented in Figure 8. In Table 1 we present the corresponding decreasing speed, as well as the required time to reach $T_{min} = 10^{-7}$, provided that the process is started at $T_{init} = 1$.

Figure 8: Trajectories associated with the cooling simulations described in table 1. The energy evolution is plotted as a function of the temperature ($x = -\log(T)$, $y = U$). Trajectories *a*, *b*, *c* have been obtained using geometrical schedules, while *d* corresponds to the proposed adaptive scheme.

Figure 9: Temperature evolution as function of time ($x = t$, $y = \log(T)$) for simulations *c* and *d*.

The result presented in Figure 9 (temperature as a function of time) shows that the proposed scheme allows staying longer at interesting temperatures while going faster when possible. Figure 10 shows a closed view of the temperature evolution at the beginning of the simulation. It shows that the cooling speed is increased, until reaching the first critical temperature. Figures 11 and 12 show details of the simulation around the first critical zone. The deceleration occurs correctly, although it is a little bit delayed.

Figure 10: Beginning of the simulation *d*. Temperature as a function of time ($x = t$, $y = \log(T)$).

Finally, in Figure 13, we compare the energy evolution as a function of time in the case of a slow piecewise geometrical schedule (simulation *c*) and of the adaptive scheme (simulation *d*). The conclusion is that the adaptive scheme performs better.

6.2 Selecting a sub-optimal behavior

The apparent advantage of the proposed approach is that it does not require launching several simulations to find the best decreasing constant with respect to the problem. The drawback is that the needed time is tremendously large. For obtaining the best possible result, the proposed adaptive scheme seems to be adequate. On the other hand, the natural advantage of the geometrical scheme is that it allows fixing an optimization time.

By imposing a lower bound on the cooling speed $A < A_{max}$, it is possible to constrain the optimization time. For instance, we have constrained $A < 1 - \exp(-10) = 0.99$. Using steps of length $\Delta_t = 20000$, it gives that the simulation can go from T_{init} to T_{min} in 35 millions of iterations, at worst. We have compared this scheme with a piecewise constant geometrical scheme with $A = 0.9994$ that reaches the minimal temperature in 37 millions of iterations. We present the result on Figure 14. The result shows that the adaptive approach is more efficient.

6.3 Case of simpler problems

In this section we consider a simpler optimization problem. We consider the model without the segments. The problem is therefore to find an optimal configuration of rectangles only (see [16, 17]).

The first simulation compares the sub-optimal cooling schedule presented in the previous section ($A < 1 - \exp(-10) = 0.99$) with the corresponding geometrical cooling scheme ($L = 2000$, $A = 0.9994$). Both of them should reach T_{min} in the same amount of time.

Figure 11: Evolution of the energy as a function of temperature, close view from the first critical zone of simulation *d*.

We show in Figure 15 the simulation result. The dark gray curve corresponds to the geometrical cooling schedule while the light gray one stands for the sub-optimal adaptive scheme. The latter clearly outperforms the former.

Finally we compared these two results with an adaptive scheme whose speed is not constrained. We present in Figure 16 the simulation result. We can see that the final energy level is much better, while the time needed is only twice what it was in the former case.

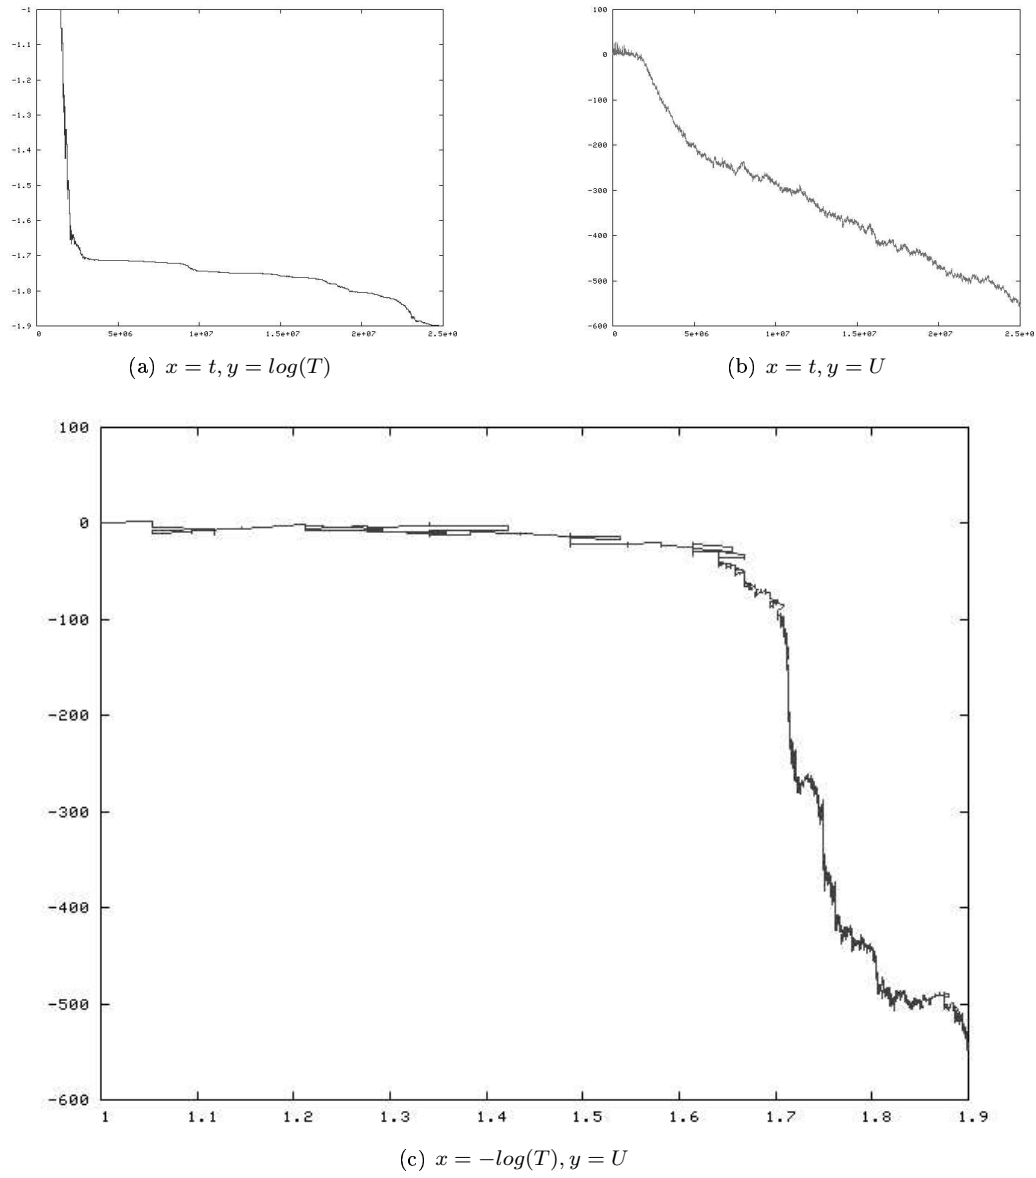

6.4 Parameters influence

The most important parameter is the length of a step Δ_t . This parameter should be set to a value that is coherent with the correlation of the Markov Chain. The other parameters, n_1 , n_2 and r are quite robust. An exhaustive evaluation of their influence should be done in the near future to study the heuristic we propose more deeply.

7 Conclusion

In this report, we have proposed an adaptive cooling schedule for simulated annealing procedures. The proposed scheme is based on experimental observations, and in particular, on the observation that some temperatures are critical. The designed scheme is based on the idea that the cooling schedule should cross these temperatures slowly, while it could go faster between two critical temperatures.

The proposed adaptive cooling scheme has proved its usefulness in practice. During his PhD work, the first author indeed extensively used it. The adaptive schedule shows several practical advantages, in addition of providing better results compared to equivalent geometrical schemes. The proposed scheme enables to set the initial temperature at an arbitrary high value, something that is usually avoided, since in the case of a geometrical scheme, it results in a waste of a large amount of computational time. Another very important advantage of this scheme, is that it allows changing the dimension of the problem (e.g. the size of the image) without further tuning of the cooling schedule.

Figure 12: Details of the critical zone, (simulation d).

Figure 13: Energy as a function of time for the slow geometrical scheme (simulation *c*) and the adaptive schedule (simulation *d*).

Even though practical experiments have shown the power of the proposed heuristic, some points still need to be carefully examined. We will conduct a proper study of the scheme, through classical problems like the Ising model or the traveling salesman problem.

Acknowledgments

The authors would like to thank the the French National Geographic Institute (IGN) for providing the images presented in this report. The first author thanks the French Defense Agency (DGA) and CNRS for partial financial support during his PhD thesis.
